It is possible to achieve Properly Functioning Condition in the uplands and riparian zones at a seral stage that does not provide the values for which we are required to manage Crown range in British Columbia. This is why the selection of the Desired Plant Community (DPC) is so important.

Desired Plant Community

The Desired Plant Community is one that produces the kind, proportion, and amount of vegetation necessary for meeting or exceeding the land use plan/activity objectives established for the site. The Desired Plant Community must be consistent with the site’s capability to produce the desired vegetation through management, land treatment, or a combination of the two.

The Desired Plant Community takes into account multiple values such as: economics, biodiversity, water quality, wildlife, fisheries, livestock forage, recreation, and quality of life. The Desired Plant Community is chosen to optimize for this mix of values, not maximize for any one value, since inevitably some values will be in conflict with others. The Desired Plant Community will, in most cases, be a seral stage to the Potential Natural Community.

However, the Ministry of Forests uses the concept of Properly Functioning Condition in combination with the Desired Plant Community when evaluating the overall health of rangelands.

Properly Functioning Condition is the foundation upon which other values can be achieved. It is a starting point, not the ultimate goal. The joint tools of Properly Functioning Condition and Desired Plant Community provide an effective means of determining whether or not our use of the land is appropriate, given the land’s capability and the values for which we as a society are required to manage.

A comparison of range condition class to seral stage

(from Process for Assessing Proper Functioning Condition, Don Prichard, USDITR1737-9-1993)
A watershed is the land drained by a stream or river system and/or associated wetlands and lakes. A watershed can be as small as a few hectares without external drainage, or as large as thousands of square kilometres, such as the Fraser River.

Uplands often comprise more than 99% of the watershed’s area, with the floodplain and stream channel making up the rest. Uplands are associated with lowlands through the flow of water, either overland or through the soil. Vegetation slows the flow of water in the uplands so that it infiltrates the soil.

A riparian zone has vegetation that, due to the presence of water, is different from the vegetation of adjacent upland areas. Typically, riparian zones are adjacent to streams or waterbodies, but they also occur adjacent to springs and seeps. Vegetation slows the flow of water on the floodplain, thereby capturing sediment and building banks. A healthy riparian zone acts as a sponge, which slowly releases water to the stream or wetland over the course of the season, thereby maintaining water flow or water levels. A stream in a healthy condition should have ready access to its floodplain during high flow periods.

Good watershed management will result in a good connection between the uplands and the riparian area, and between the stream, wetland, or lake and the floodplain or associated riparian area.

Range monitoring helps with determining if desired management goals are being achieved. Range ecosystems determine trends in range ecosystems over time.

The components of a watershed

What is a watershed?

A watershed can be an administrative area for management plans. Assessments of areas in the watershed, using appropriate methods such as those considering stream dynamics and plant communities, can help with determining if the desired management goals are being achieved.

A

The concept of Properly Functioning Condition (PFC) has its origin in hydrology and watershed management. A properly functioning watershed should capture precipitation where it falls, store it in the soil profile, move it slowly downslope to the riparian zone, and then slowly and safely release it into streams, rivers, wetlands, and lakes. Several parameters are evaluated in field assessments of the stream or wetland feature, the adjacent riparian area, and the contributing uplands. These are: stream channel or wetland properties, flow regime, hydrology/soil, erosion/deposition, the biotic community, nutrient inputs, and water quality. Areas are rated as “Properly Functioning Condition,” “at risk,” or “non-functional,” depending on the observations made.

Functionality checklists for uplands, streams, and wetlands/lakes are completed for relatively homogeneous areas and provide an objective assessment and record of the health of the riparian feature, its adjacent riparian zone, and the contributing uplands. Follow-up monitoring is used to determine if management practices on the land are leading to improvement or decline in functionality.

Potential Natural Community

The Potential Natural Community (PNC) is the plant community that would become established on a range (ecological) site if all successional stages were completed without interferences by humans under today’s environmental conditions. The plant community is seen as dynamic, not static. For practical purposes, the Potential Natural Community and the Climates are the same except that the Potential Natural Community recognizes that some irreversible changes have occurred to plant communities due to the influence of humans (weed introductions, climatic change, etc.). In these cases the plant community may be stalled at an earlier seral stage or it may be dominated by an
